We study the generalized susceptibilities from kurtosis which is known as the  $\chi_4^B/\chi_2^B$  to the  $\chi_8^B/\chi_2^B$ . The results are obtained under the finite temperature and baryon density. We give the comparison of our results with the lattice QCD results under the vanishing  $\mu_B$ . We get the numerical results under the Polyakov-quark-meson (PQM) model with the functional renormalisation group (FRG) approach.

FIG. 1. Diagrammatic representation of the QCD flow equation within the fRG approach. Lines of different types on the r.h.s. of the equation stand for the full propagators of gluon, ghost, quark, and meson, respectively. Note that the mesonic degree of freedom is denoted by double lines with opposite arrows. The crossed circles represent the regulators in the flow equation.

## I. INTRODUCTION

### II. QCD AND LOW ENERGY EFFECTIVE THEORIES WITHIN THE FRG APPROACH

An generic Euclidian quantum field theory is completely described by its effective action  $\Gamma[\Phi]$ , where  $\Phi$  is used to denote an aggregate of all fields in the theory. In the fRG approach, this full quantum effective action is resolved by interpolating it as a function of a renormalization group (RG) scale  $k$ , i.e.,  $\Gamma_k[\Phi]$ , successively, starting from the respective classical action  $S[\Phi]$  at a very high ultraviolet (UV) scale, say  $\Lambda$ , towards the infrared (IR) limit  $k \rightarrow 0$  with  $\Gamma[\Phi] = \Gamma_{k=0}[\Phi]$ . For more details about the formalism of fRG, see, e.g., [1] as well as [2, 3].

To be specific, the flow equation for QCD, which describes the evolution of its effective action with the RG scale  $k$ , is shown in Fig. 1 diagrammatically. As one could see, the QCD flow receives contributions not only from the gluon, ghost and the quark, i.e., the fundamental partonic degrees of freedom in QCD, but also from hadrons, such as mesons, which are composite or emergent degrees of freedom, and are generated dynamically through strong interactions when the RG scale is reduced down to the nonperturbative regime of the low energy QCD. Recent first-principle QCD calculations within fRG indicate

that this transition, from the partonic to composite degrees of freedom, takes place in a narrow regime located at  $k \sim 1$  GeV [4–7]. The flow of the QCD effective action corresponding to the diagrams in Fig. 1 can be written as follows,

$$\begin{aligned} \partial_t \Gamma_k[\Phi] = & \frac{1}{2} \text{Tr} \left( G_{AA,k} \partial_t R_{A,k} \right) - \text{Tr} \left( G_{c\bar{c},k} \partial_t R_{c,k} \right) \\ & - \text{Tr} \left( G_{q\bar{q},k} \partial_t R_{q,k} \right) + \frac{1}{2} \text{Tr} \left( G_{\phi\phi,k} \partial_t R_{\phi,k} \right), \end{aligned} \quad (1)$$

with  $\Phi = (A, c, \bar{c}, q, \bar{q}, \phi)$ , where  $G$ 's and  $R$ 's are the propagators and regulators of different fields, respectively. Note that the scale dependence of these quantities is explicitly indicated with a suffix  $k$ . The RG time in Eq. (1) is defined by  $t = \ln(k/\Lambda)$ , with the initial UV scale  $\Lambda$ . We are not going to discuss details of the QCD flow in Eq. (1) here, and interested readers are strongly suggested to refer to, e.g., [4–13] for recent progress in understanding of QCD or Yang-Mills theory in the vacuum and at finite temperature and density within the fRG approach, and also [14–20] for QCD related review articles of fRG.

As mentioned above, the transition of the degrees of freedom, from the partonic ones in the perturbative regime of high energy to the hadronic ones in the non-perturbative region of low energy, is realized through the dynamical hadronization in the fRG approach. With the help of the technique of dynamical hadronization, composite operators of resonated channels, e.g., the  $\sigma$ - $\pi$  channel, i.e., the scalar-pseudoscalar one in the low energy QCD, which are most relevant to the dynamics of the system, are bosonized or Hubbard-Stratonovich transformed successively with the evolution of RG scale. For more details, see, e.g., [7, 15, 21–23].

In a recent first-principle fRG calculation to QCD, it has been shown clearly that a sequential decoupling of the gluon, quark, and mesonic degrees of freedom from the system with decreasing RG scale, results in a natu-

ral emergence of the low energy effective theory (LEFT) when the scale  $k \lesssim 1$  GeV [7]. The fRG formalism is ideally suited to the description of a phenomenon of emergence, which usually involves energy scale of different hierarchies, characteristic to different degrees of freedom. When the scale  $k$  is high and the system is located in the perturbative region, the only relevant degrees of freedom in QCD are the gluon and quark, and the hadronic or mesonic ones are irrelevant due to their large masses. When  $k$  decreases below  $\sim 1$  GeV, the gluon develops a significant mass gap in the low momentum region, and thus decouples from the system. The dynamics is taken over by the emergent composite degrees of freedom, e.g. mesons, in particular the  $\pi$  meson, which is in essence the Goldstone boson related to the spontaneously breaking chiral symmetry in the low energy QCD, and is the lightest hadron of mass  $\sim 140$  MeV in the vacuum.

The direct consequence of the natural emergence of LEFT is that, if the flow equation of QCD in Eq. (1) is evolved at a starting scale, in which the glue sector has already significantly been suppressed by the gluon mass gap, say  $\Lambda \sim 1$  GeV, it is safe and legitimate to disregard quantum fluctuations of the glue sector, i.e., the first two diagrams in Fig. 1. Hence we are left with a scale dependent effective action, only composed of the matter sector fields, namely, the quark and meson, which reads

$$\Gamma_k[\Phi] = \int_x \left\{ Z_{q,k} \bar{q} \left[ \gamma_\mu \partial_\mu - \gamma_0 (\hat{\mu} + ig A_0) \right] q + \frac{1}{2} Z_{\phi,k} (\partial_\mu \phi)^2 + h_k \bar{q} (T^0 \sigma + i \gamma_5 \vec{T} \cdot \vec{\pi}) q + V_k(\rho, A_0) - c\sigma \right\}, \quad (2)$$

with a reduction of the involved species of fields  $\Phi = (q, \bar{q}, \phi)$ , and the shorthand notation for the space-time integral  $\int_x = \int_0^{1/T} dx_0 \int d^3x$ . Note that in this work we only consider the case of  $N_f = 2$  flavor quark, i.e., the quark field  $q = (u, d)^T$  in the action Eq. (2). The meson field  $\phi = (\sigma, \vec{\pi})$ , being in the adjoint representation of group  $U_V(N_f) \times U_A(N_f)$  in the flavor space, is coupled with the quark field through the Yukawa coupling. Here  $T^0$  and  $T^i$ 's ( $i = 1, 2, \dots, N_f^2 - 1$ ) are the generators of  $U(N_f)$  group, denoted collectively as  $T^a$ 's, with the normalization  $\text{Tr}(T^a T^b) = \frac{1}{2} \delta^{ab}$ , which yields  $T^0 = \frac{1}{\sqrt{2N_f}} \mathbb{1}_{N_f \times N_f}$ .  $Z_{q,k}$  and  $Z_{\phi,k}$  are the wave function renormalization for the quark and meson fields, respectively. Note that the wave function renormalizations, as well as the Yukawa coupling  $h_k$  and the effective potential  $V_k$  to be discussed in the following, are dependent on the RG scale  $k$ .

Quantum fluctuations of the glue sector are suppressed in the low energy region due to the large gluon mass gap as discussed above, and consequently it is reasonable to neglect their corresponding contributions in the flow equation of QCD in Fig. 1 or Eq. (1). The gluonic background field is, however, of significant importance for the

QCD thermodynamics. In Eq. (2) the temporal component of the gluonic background field  $A_0$  is encoded, which is responsible for the quark confinement in the statistical sense of thermodynamics, see, e.g., [24–27] for more details. Therefore, the effective potential in Eq. (2) reads

$$V_k(\rho, A_0) = V_{\text{glue},k}(A_0) + V_{\text{mat},k}(\rho, A_0), \quad (3)$$

where the first term on the right-hand side is due to the temporal gluonic background field  $A_0$ , which can also be formulated in terms of the Polyakov loop  $L(A_0)$ . More details about  $V_{\text{glue},k}$  used in this work can be found in Appendix A. The matter part of the effective potential  $V_{\text{mat},k}$  arises from the quark and meson diagrams in Fig. 1, which is dependent on the meson field through  $\rho = \phi^2/2$ . Clearly,  $V_{\text{mat},k}$  is  $SU_A(2)$  or  $O(4)$  invariant, which guarantees that the chiral symmetry is preserved on the level of interactions. The explicit breaking of the chiral symmetry is attributed to the linear term  $-c\sigma$  in Eq. (2), which is also related to a nonvanishing value of the current quark mass. The quark chemical potential  $\hat{\mu} = \text{diag}(\mu_u, \mu_d)$  in the first line of Eq. (2) is a diagonal matrix in the flavor space, and  $\mu = \mu_u = \mu_d$  is assumed throughout this work. The quark chemical potential is related to the baryon chemical potential via  $\mu = \mu_B/3$ .

In the scale regime of LEFT, as we have discussed above, the flow equation of the effective action in Eq. (1) is reduced to

$$\partial_t \Gamma_k[\Phi] = -\text{Tr} \left( G_{q\bar{q},k} \partial_t R_{q,k} \right) + \frac{1}{2} \text{Tr} \left( G_{\phi\phi,k} \partial_t R_{\phi,k} \right), \quad (4)$$

where  $R_{q,k}$  and  $R_{\phi,k}$  are the regulators for the quark and meson fields, respectively, and their explicit expressions are given in Appendix B. The full propagators read

$$G_{q\bar{q}/\phi\phi,k} = \left( \frac{1}{\Gamma_k^{(2)}[\Phi] + R_k} \right)_{q\bar{q}/\phi\phi}, \quad (5)$$

with  $\Gamma_k^{(2)}[\Phi] = \delta^2 \Gamma_k[\Phi] / (\delta \Phi_{i_1} \delta \Phi_{i_2})$ , where different species of fields are distinguished with the help of the subscripts in  $\Phi_{i_1/i_2}$ . Inserting the effective action (2) into the flow equation (4), one is led to the flow equation for the effective potential of the matter sector, as follows

$$\begin{aligned} \partial_t V_{\text{mat},k}(\rho) = & \frac{k^4}{4\pi^2} \left[ (N_f^2 - 1) l_0^{(B,4)}(\tilde{m}_{\pi,k}^2, \eta_{\phi,k}; T) \right. \\ & + l_0^{(B,4)}(\tilde{m}_{\sigma,k}^2, \eta_{\phi,k}; T) \\ & \left. - 4N_c N_f l_0^{(F,4)}(\tilde{m}_{q,k}^2, \eta_{q,k}; T, \mu) \right], \quad (6) \end{aligned}$$

where the threshold functions  $l_0^{(B/F,4)}$  are presented in Appendix B, and the dimensionless renormalized quark

and meson masses read

$$\tilde{m}_{q,k}^2 = \frac{h_k^2 \rho}{2k^2 Z_{q,k}^2}, \quad \tilde{m}_{\pi,k}^2 = \frac{V'_{\text{mat},k}(\rho)}{k^2 Z_{\phi,k}}, \quad (7)$$

$$\tilde{m}_{\sigma,k}^2 = \frac{V'_{\text{mat},k}(\rho) + 2\rho V''_{\text{mat},k}(\rho)}{k^2 Z_{\phi,k}}. \quad (8)$$

The anomalous dimensions for the quark and meson fields in Eq. (6) are defined as

$$\eta_{q,k} = -\frac{\partial_t Z_{q,k}}{Z_{q,k}}, \quad \eta_{\phi,k} = -\frac{\partial_t Z_{\phi,k}}{Z_{\phi,k}}, \quad (9)$$

respectively. Accordingly, projecting the flow in Eq. (4) onto the one-particle irreducible (1PI) two-point function of the meson, one is readily to obtain

$$\eta_{\phi,k} = -\frac{1}{3Z_{\phi,k}} \delta_{ij} \frac{\partial}{\partial(|\mathbf{p}|^2)} \frac{\delta^2 \partial_t \Gamma_k}{\delta \pi_i(-p) \delta \pi_j(p)} \Big|_{\substack{p_0=0 \\ \mathbf{p}=0}}, \quad (10)$$

where the spacial component is employed. Note that in the case of finite temperature and density, the  $O(4)$  rotation symmetry in the  $4-d$  Euclidean space is broken, and as a matter of fact, the mesonic anomalous dimension extracted above is different from that projected onto the temporal component. In another word,  $\eta_{\phi,k}$  is split into  $\eta_{\phi,k}^\perp$  and  $\eta_{\phi,k}^\parallel$ , which are transverse and longitudinal to the heat bath, respectively, at finite temperature and density. The influences of the splitting of  $\eta_{\phi,k}$  on the thermodynamics and baryon number fluctuations have been investigated in detail [28], and it has been found that the impact is small. Therefore, it is reasonable to disregard the splitting of anomalous dimensions, and  $\eta_{\phi,k} = \eta_{\phi,k}^\perp = \eta_{\phi,k}^\parallel$ , as well as that for the quark anomalous dimension in the following, is assumed throughout this work. In the same way, the quark anomalous dimension is obtained by projecting the relevant flow onto the vector channel of the 1PI quark-antiquark correlation function, as follows

$$\eta_q = \frac{1}{4Z_{q,k}} \times \text{Re} \left[ \frac{\partial}{\partial(|\mathbf{p}|^2)} \text{tr} \left( i\gamma \cdot \mathbf{p} \left( -\frac{\delta^2}{\delta \bar{q}(p) \delta q(p)} \partial_t \Gamma_k \right) \right) \right] \Big|_{\substack{p_0=0 \\ \mathbf{p}=0}}, \quad (11)$$

where the external spacial momentum is chosen to be zero as same as the mesonic one, since the vanishing momentum is most relevant to the flow of effective potential in Eq. (6). Note that the lowest mode of the fermionic Matsubara frequency is nonvanishing and we designate it here as  $p_{0,ex}$ , to be described in Appendix B. Moreover, the expression in the square bracket in (11) is complex-valued, rather than real, when the chemical potential is nonzero. This artifact stems from the naive truncation

of the external frequency, that is resolved through a re-summation of the external frequency of quark [29]. The flow equation of the Yukawa coupling is readily obtained via the projection of the 1PI quark-antiquark correlation function on the scalar channel, which reads

$$\partial_t h_k = \frac{1}{2\sigma} \text{Re} \left[ \text{tr} \left( -\frac{\delta^2}{\delta \bar{q}(p) \delta q(p)} \partial_t \Gamma_k \right) \right] \Big|_{\substack{p_0=0 \\ \mathbf{p}=0}}. \quad (12)$$

The explicit expressions for the meson and quark anomalous dimensions, and the flow of the Yukawa coupling can be found in Appendix B.

### III. THERMODYNAMICS AND HYPER-ORDER BARYON NUMBER FLUCTUATIONS

The thermodynamical potential density in the LEFT at finite temperature and nonzero baryon chemical potential is readily obtained from the effective action in Eq. (2), which reads

$$\Omega[T, \mu_B] = V_{\text{glue}}(L, \bar{L}) + V_{\text{mat},k=0}(\rho) - c\sigma, \quad (13)$$

where the gluonic background field  $A_0$  has been reformulated in terms of the Polyakov loop  $L$  and its complex conjugate  $\bar{L}$ . The matter sector of the effective potential is integrated out towards the IR limit  $k = 0$ , while the glue sector is independent of  $k$ , see Appendix A. Note that the Polyakov loop and the meson field are on their respective equations of motion, and the effective potential in Eq. (13) is normalized to zero in vacuum. The pressure of the system is directly related to the thermodynamical potential, as follows

$$p = -\Omega[T, \mu_B]. \quad (14)$$

The generalized susceptibility of the baryon number  $\chi_n^B$  is defined through the  $n$ -order derivative of the pressure w.r.t. the baryon chemical potential, to wit,

$$\chi_n^B = \frac{\partial^n}{\partial(\mu_B/T)^n} \frac{p}{T^4}. \quad (15)$$

The generalized susceptibilities are related to various cumulants of the baryon number distribution, which can be measured in heavy-ion collision experiments through the cumulants of its proxy, i.e., the net proton distribution, see, e.g. [30] for details. For the lowest four orders, one is led to

$$\chi_1^B = \frac{1}{VT^3} \langle N_B \rangle, \quad \chi_2^B = \frac{1}{VT^3} \langle (\delta N_B)^2 \rangle, \quad (16)$$

$$\chi_3^B = \frac{1}{VT^3} \langle (\delta N_B)^3 \rangle, \quad (17)$$

$$\chi_4^B = \frac{1}{VT^3} \left( \langle (\delta N_B)^4 \rangle - 3 \langle (\delta N_B)^2 \rangle^2 \right), \quad (18)$$

with  $\langle \dots \rangle$  denoting the ensemble average and  $\delta N_B = N_B - \langle N_B \rangle$ . Thus the mean value of the net baryon number of the system is given by  $M = VT^3 \chi_1^B$ , the variance  $\sigma^2 = VT^3 \chi_2^B$ , skewness  $S = \chi_3^B / (\chi_2^B \sigma)$ , and the kurtosis  $\kappa = \chi_4^B / (\chi_2^B \sigma^2)$ , respectively.

In this work emphasis is, however, put on the baryon number fluctuations of order higher than the fourth, i.e.,  $\chi_n^B$ 's ( $n > 4$ ), which are named hyper-order baryon number fluctuations. As same as the low-order ones, the hyper-order susceptibilities are also connected to their respective cumulants, and their relations, taking the fifth through eighth ones for instance, are given as follows

$$\chi_5^B = \frac{1}{VT^3} \left( \langle (\delta N_B)^5 \rangle - 10 \langle (\delta N_B)^2 \rangle \langle (\delta N_B)^3 \rangle \right), \quad (19)$$

$$\begin{aligned} \chi_6^B = \frac{1}{VT^3} \left( \langle (\delta N_B)^6 \rangle - 15 \langle (\delta N_B)^4 \rangle \langle (\delta N_B)^2 \rangle \right. \\ \left. - 10 \langle (\delta N_B)^3 \rangle^2 + 30 \langle (\delta N_B)^2 \rangle^3 \right), \end{aligned} \quad (20)$$

$$\begin{aligned} \chi_7^B = \frac{1}{VT^3} \left( \langle (\delta N_B)^7 \rangle - 21 \langle (\delta N_B)^5 \rangle \langle (\delta N_B)^2 \rangle \right. \\ \left. - 35 \langle (\delta N_B)^4 \rangle \langle (\delta N_B)^3 \rangle \right. \\ \left. + 210 \langle (\delta N_B)^3 \rangle \langle (\delta N_B)^2 \rangle^2 \right), \end{aligned} \quad (21)$$

$$\begin{aligned} \chi_8^B = \frac{1}{VT^3} \left( \langle (\delta N_B)^8 \rangle - 28 \langle (\delta N_B)^6 \rangle \langle (\delta N_B)^2 \rangle \right. \\ \left. - 56 \langle (\delta N_B)^5 \rangle \langle (\delta N_B)^3 \rangle - 35 \langle (\delta N_B)^4 \rangle^2 \right. \\ \left. + 420 \langle (\delta N_B)^4 \rangle \langle (\delta N_B)^2 \rangle^2 \right. \\ \left. + 560 \langle (\delta N_B)^3 \rangle^2 \langle (\delta N_B)^2 \rangle - 630 \langle (\delta N_B)^2 \rangle^4 \right). \end{aligned} \quad (22)$$

#### IV. NUMERICAL RESULTS AND DISCUSSIONS

In this section we would like to present our calculated results and compare them with the relevant lattice calculations. Implications of our prediction for the hyper-order baryon number fluctuations in the heavy-ion collision experiments will also be discussed. But before we do that, the scales in the LEFT and OCD have to be matched.

##### A. Matching the scales in LEFT and OCD

Usually the scale in LEFT and that in QCD do not agree with each other exactly, and a direct consequence is that the pseudocritical temperature of the chiral phase

crossover, i.e., the value of  $T_c$  at  $\mu_B = 0$  is different in the LEFT and QCD. Although it is not a real phase transition, the benchmark value of  $T_c$  is well determined through, e.g., the chiral condensate, chiral susceptibilities, etc. Recently, two lattice collaborations, the HotQCD collaboration and the Wuppertal-Budapest collaboration find  $T_c = 156.5 \pm 1.5$  MeV [35] and  $T_c = 158.0 \pm 0.6$  MeV, respectively. Furthermore, the scale is also affected by the number of quark flavors. As shown in the effective action in Eq. (2), only the  $N_f = 2$  flavor quarks, i.e., light quarks  $u$  and  $d$ , are included in the LEFT in this work, while in lattice simulations besides the light quarks, dynamics of the strange quark is also taken into account. Thus there should be a mismatch of the scale resulting from the different systems of  $N_f = 2$  and  $N_f = 2 + 1$  flavor quarks.

We denote the temperature and the baryon chemical potential in the LEFT as  $T_{LEFT}$  and  $\mu_{BLEFT}$ , respectively, where the suffix is used to distinguish them from  $T$  and  $\mu_B$  in QCD or lattice simulations. In order to resolve the mismatch of the scale in LEFT and OCD, a simple linear relation between them both for the temperature and chemical potential is assumed, to wit,

$$T_{LEFT} = c_T T, \quad \mu_{BLEFT} = c_\mu \mu_B, \quad (23)$$

where the constant coefficients  $c_T$  and  $c_\mu$  are to be determined.

The coefficient  $c_T$  in Eq. (23) is fixed through fitting the LEFT curve of  $R_{42}^B = \chi_4^B / \chi_2^B$  in the left panel of Fig. 2, i.e., the kurtosis of the baryon number distribution  $\kappa \sigma^2 = R_{42}^B$ , as a function of the physical temperature  $T$  with  $\mu_B = 0$  in comparison to the lattice results. It is found that the LEFT within fRG provides the best description of the lattice  $\kappa \sigma^2$  with  $c_T = 1.247(12)$ . To proceed, the constant  $c_\mu$  in Eq. (23) is determined by the curvature of the phase boundary, which is defined as the quadratic expansion coefficient of the pseudocritical temperature as a function of the baryon chemical potential around  $\mu_B = 0$ , i.e.,

$$\frac{T_c(\mu_B)}{T_c} = 1 - \kappa \left( \frac{\mu_B}{T_c} \right)^2 + \lambda \left( \frac{\mu_B}{T_c} \right)^4 + \dots, \quad (24)$$

with the curvature  $\kappa$ , where the next fourth order expansion coefficient  $\lambda$  is neglected in our calculations, since it hardly plays any role in the region of baryon chemical potential concerned in this work, e.g., up to  $\mu_B \sim 400$  MeV in the following, due to its small value.  $T_c$  in Eq. (24) is the pseudocritical temperature at  $\mu_B = 0$ . Note that the curvature is invariant only if the chemical potential and temperature are rescaled with the same value, and thus the curvature  $\kappa_{LEFT}$  in the LEFT would not be modified if one has  $c_\mu = c_T$  in Eq. (23). By employing the order parameter of the chiral phase transition, i.e., the expectation value of the sigma field  $\langle \sigma \rangle$  in Eq. (2), we obtain  $\kappa_{LEFT} = 0.0193$  in the  $N_f = 2$  flavor LEFT. For more discussions about the phase boundary and curvature, see, e.g., [7]. This value of  $\kappa_{LEFT}$  is a bit larger

FIG. 2.  $R_{42}^B = \chi_4^B / \chi_2^B$  (left panel),  $R_{62}^B = \chi_6^B / \chi_2^B$  (middle panel), and  $R_{82}^B = \chi_8^B / \chi_2^B$  (right panel) as functions of the temperature with vanishing baryon chemical potential ( $\mu_B = 0$ ). Results obtained with the low energy effective theory within fRG approach are compared with lattice results from the HotQCD collaboration [31–33] and the Wuppertal-Budapest collaboration [34]. The inset in the plot of  $R_{82}^B$  shows its zoom-out view.

FIG. 3.  $R_{10,2}^B = \chi_{10}^B / \chi_2^B$  as a function of the temperature with  $\mu_B = 0$ , predicted by the LEFT within the fRG approach.

than recent  $N_f = 2 + 1$  lattice results, e.g.,  $\kappa = 0.015(4)$  in [35],  $\kappa = 0.0149(21)$  in [36],  $\kappa = 0.0153(18)$  in [37]. This mismatch of the curvature between the LEFT and lattice QCD, however, is cured through a suitable choice for the ratio  $c_\mu / c_T$  in Eq. (23), and one readily arrives at

$$c_\mu = c_T \left( \frac{\kappa}{\kappa_{LEFT}} \right)^{1/2}. \quad (25)$$

Substituting  $\kappa_{LEFT} = 0.0193$ ,  $\kappa = 0.0153(18)$ , and  $c_T = 1.247(12)$  into the equation above, one obtains  $c_\mu = 1.110(66)$ .

To sum up, in this section the scales between the LEFT and QCD have been matched by resorting to two observables, i.e.,  $R_{42}^B$  as a function of  $T$  at vanishing chemical potential and the curvature of phase boundary  $\kappa$ , which are both quite relevant to predictions of the hyper-order baryon number fluctuations at finite temperature and densities, to be discussed in the following.

## B. Hyper-order baryon number fluctuations

As we have discussed above, the LEFT has been calibrated by use of the curvature of phase boundary and the kurtosis of baryon number distribution as a function of  $T$  with  $\mu_B = 0$ , via a detailed comparison with recent lattice results. Consequently, one could use the LEFT to make predictions for the dependence of  $R_{42}^B$  on the chemical potential, as well as the hyper-order baryon number fluctuations at finite temperature and density. In the middle and right panels of Fig. 2,  $R_{62}^B = \chi_6^B / \chi_2^B$  and  $R_{82}^B = \chi_8^B / \chi_2^B$  are shown versus the temperature with vanishing  $\mu_B$ , respectively, and in the same way the LEFT and lattice QCD results are compared. Apparently, one observes that, with the increase of the order of fluctuations, errors of lattice calculation increase dramatically. Specifically, the eighth-order fluctuations  $R_{82}^B$  obtained by the two collaborations show a significant quantitative difference, although they are roughly consistent with each other qualitatively. It is found that the predicted hyper-order baryon number fluctuations from the LEFT within the fRG, are in qualitative agreement with both lattice results, and even consistent with the Wuppertal-Budapest result quantitatively within the errors. Moreover, we have also computed baryon number fluctuations of orders even up to the tenth in the LEFT, and the relevant result  $R_{10,2}^B = \chi_{10}^B / \chi_2^B$  is presented in Fig. 3, where the chemical potential is chosen to be vanishing. Note that no lattice results for the tenth-order fluctuation are available for the moment, and the dependence of  $R_{10,2}^B$  on the temperature in Fig. 3 is a pure prediction by the LEFT within the fRG approach, which needs to be confirmed by other calculations, e.g., lattice QCD, in the future.

To proceed, we consider the chemical potential dependence of baryon number fluctuations. Expanding the pressure in Eq. (14) in powers of  $\hat{\mu}_B \equiv \mu_B / T$  around

FIG. 4.  $R_{42}^B$  (left panel) and  $R_{62}^B$  (right panel) as functions of  $\mu_B/T$  with  $T = 155$  MeV and  $T = 160$  MeV. Calculation of LEFT within the fRG approach is compared with lattice QCD by the HotQCD collaboration [33] and the Wuppertal-Budapest collaboration [34]. Note that the comparison of  $R_{42}^B$  between HotQCD and LEFT is presented in the inlay of left panel, in order to improve the readability of presentation.

FIG. 5. Comparison between the direct full calculation of baryon number fluctuations  $R_{42}^B$  (left panel) and  $R_{62}^B$  (right panel) via Eq. (15) and the Taylor expansion in Eqs. (27) (28) (29). Both calculations are performed within the LEFT-fRG approach, and  $R_{42}^B$ ,  $R_{62}^B$  are plotted as functions of  $\mu_B/T$  with  $T = 155$  MeV and  $T = 160$  MeV.

$\hat{\mu}_B = 0$ , one is led to

$$\frac{p}{T^4} = \frac{p}{T^4} \Big|_{\hat{\mu}_B=0} + \sum_{i=1}^{\infty} \frac{\chi_{2i}^B|_{\hat{\mu}_B=0}}{(2i)!} \hat{\mu}_B^{2i}. \quad (26)$$

Truncating the Taylor expansion above up to order of  $\hat{\mu}_B^8$  and employing Eq. (15), we obtain the expanded baryon

number fluctuations in the first several orders, to wit,

$$\begin{aligned} \chi_2^B &\simeq \chi_2^B|_{\hat{\mu}_B=0} + \frac{\chi_4^B|_{\hat{\mu}_B=0}}{2!} \hat{\mu}_B^2 + \frac{\chi_6^B|_{\hat{\mu}_B=0}}{4!} \hat{\mu}_B^4 \\ &\quad + \frac{\chi_8^B|_{\hat{\mu}_B=0}}{6!} \hat{\mu}_B^6, \end{aligned} \quad (27)$$

$$\chi_4^B \simeq \chi_4^B|_{\hat{\mu}_B=0} + \frac{\chi_6^B|_{\hat{\mu}_B=0}}{2!} \hat{\mu}_B^2 + \frac{\chi_8^B|_{\hat{\mu}_B=0}}{4!} \hat{\mu}_B^4, \quad (28)$$

$$\chi_6^B \simeq \chi_6^B|_{\hat{\mu}_B=0} + \frac{\chi_8^B|_{\hat{\mu}_B=0}}{2!} \hat{\mu}_B^2. \quad (29)$$

In Fig. 4 we show the lattice results  $\chi_4^B/\chi_2^B$  and  $\chi_6^B/\chi_2^B$  based on the Taylor expansion above, and the fluctuations at vanishing chemical potential, viz.  $\chi_i^B|_{\hat{\mu}_B=0}$

FIG. 6.  $R_{42}^B$  (left panel),  $R_{62}^B$  (middle panel), and  $R_{82}^B$  (right panel) as functions of the temperature at several values of  $\mu_B$ , computed from LEFT within the fRG approach. Insets in each plot show their respective zoom-out view.

( $i = 2, 4, 6, 8$ ) and relevant results in Fig. 2, from the HotQCD collaboration [33] and the Wuppertal-Budapest collaboration [34]. Moreover,  $\chi_n^B$ 's in Eq. (15) could also be computed directly in the LEFT within the fRG approach, without resorting to the Taylor expansion, and the relevant results are presented in Fig. 4 for comparison. Here we choose two values of the temperature, and as expected, the LEFT result for the dependence of  $R_{42}^B$  and  $R_{62}^B$  on the chemical potential, agrees with both lattice results qualitatively, and is even quantitatively consistent with the Wuppertal-Budapest result. Moreover, it is of high interest to investigate the convergence of Taylor expansion in Eqs. (27) (28) (29), via a comparison to the full calculation of baryon number fluctuations in Eq. (15). We have done both calculations in the LEFT-fRG approach, and the relevant results are shown in Fig. 5. One observes that the Taylor expansion agrees well with the full calculation for  $R_{42}^B$  with  $\mu_B/T$  going up to 1.2, but the convergence is less pronounced for the higher-order fluctuation  $R_{62}^B$ , and there is a sizable difference between these two calculations even  $\mu_B/T \sim 0.8$ , as shown in the right panel of Fig. 5.

In Fig. 6  $R_{42}^B$ ,  $R_{62}^B$  and  $R_{82}^B$  are depicted as functions of  $T$  with several values of  $\mu_B$ , which are calculated in LEFT with the fRG approach. Relevant results in Fig. 2 for  $\mu_B = 0$  are presented as well, in order to highlight effects of the finite baryon chemical potential, whose value is increased from zero to 400 MeV. One observes that both the magnitude and error of the fluctuations, in particular the high-order ones, grow with the increasing chemical potential. Due to the rapid increase of error for very high-order fluctuations at large baryon chemical potential, e.g.,  $R_{82}^B$  with  $\mu_B \gtrsim 200$  MeV, it is reasonable to expect that the LEFT is losing its capability of making predictions in these regimes.

In the following we would like to confront theoretical predictions on the baryon number fluctuations with experimental measurement. Frankly speaking, a direct comparison between the theory and experiment is a challenging task, or even impossible within the setup in this work. This is due to the fact that experimental data are affected by many factors, e.g., acceptance of the detec-

|                       |     |      |      |     |     |      |      |      |     |

TABLE I. Chemical freeze-out parameters  $\mu_{B_{CF}}$  and  $T_{CF}$ , and the pseudocritical temperature  $T_c$  for different center-of-mass energies per nucleon pair  $\sqrt{s_{NN}}$ , and see text for details.

tor such as the transverse momentum  $p_T$  range, rapidity window and the centrality dependence [38–42], cf. also [30, 43] for more details, volume fluctuations [44], global baryon number conservation [45, 46], resonance decays [47], etc. They constitute the non-critical contributions to fluctuation observables in experiments, and pinning down their contributions plays a pivotal role in identifying the critical signals in the BES experiment. Additionally, more important is that the critical fluctuations in heavy ion collision take place in a dynamical process, rather not static, which necessitates a theoretical description of dynamics of critical fluctuations, with dynamical evolution and nonequilibrium effects encoded. For more details about recent progress on the dynamics of critical fluctuations in QCD, see [48] and references therein.

In this work we will not take into account the non-critical and dynamical effects discussed above when the theoretical results are confronted with experiments, but rather assume that the measured cumulants of the net-proton multiplicity distribution at a given collision energy, with other collision parameters e.g., the centrality and rapidity range fixed, is in one-by-one correspondence to the calculated fluctuations in Eq. (15) with one value of  $T$  or  $\mu_B$ . It is reasonable to attribute the values of  $T$  and  $\mu_B$  to be the ones when the chemical freeze-out occurs, viz.  $T_{CF}$  and  $\mu_{B_{CF}}$ . Such an approach for the comparison is usually employed in fluctuation studies of equilibrium QCD matter within functional methods or lattice simulations [33, 49, 50]. Note, however, that because of the reasons we have outlined above, results of

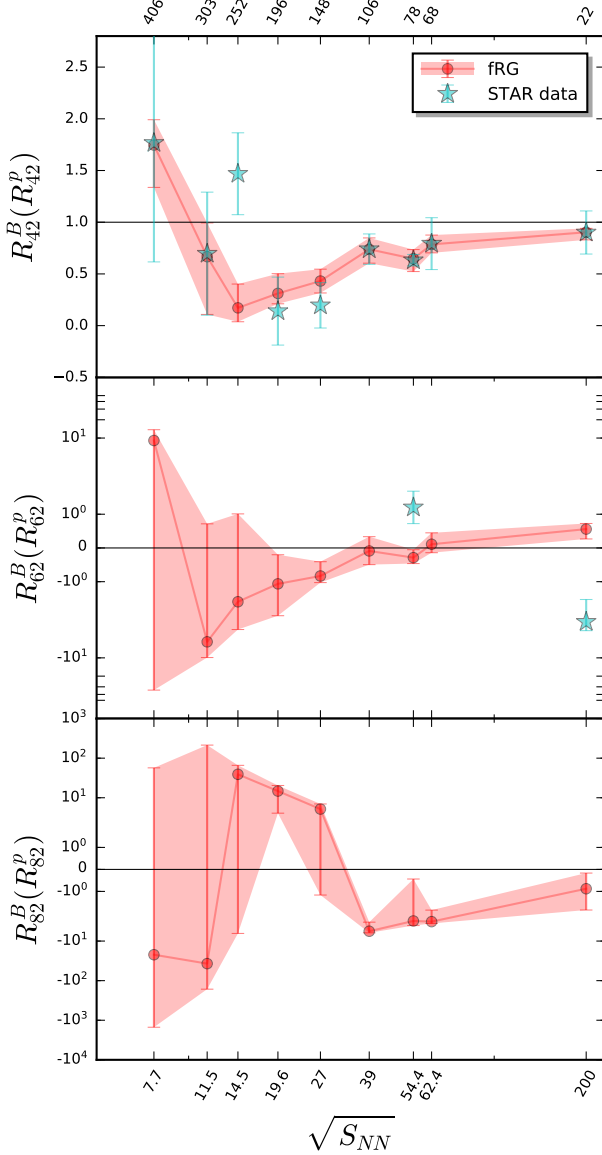

FIG. 7.  $R_{32}^B$  (upper left),  $R_{42}^B$  (lower left),  $R_{62}^B$  (upper right), and  $R_{82}^B$  (lower right) as functions of the collision energy, calculated in LEFT within the fRG approach on the freeze-out line and the pseudocritical line, respectively. Experimental data from the STAR collaboration are also shown for comparison, where  $R_{32}^p$  (upper left) and  $R_{42}^p$  (lower left) are the skewness and kurtosis of the net-proton distributions measured in Au+Au central (0-5%) collisions [40], and  $R_{62}^p$  (upper right) is the preliminary result on the six-order cumulant of the net-proton distribution at  $\sqrt{s_{NN}}=200$  GeV and 54.4 GeV with centrality 0-40% [41, 42].

comparison between the theory and experiment within this simplified approach should be taken with a grain of salt. As we will see below, the theoretically predicted dependence of baryon number fluctuations on the collision energy is less sensitive to  $\mu_{B_{CF}}$  in contradistinction to  $T_{CF}$ . Hence we adopt a phenomenological relation be-

tween the freeze-out chemical potential and the center-of-mass energy per nucleon pair  $\sqrt{s_{NN}}$ , which reads

$$\mu_{B_{CF}} = \frac{a}{1 + 0.288\sqrt{s_{NN}}}, \quad (30)$$

with  $a = 1307.5$  MeV, which is obtained from the analysis of hadron yields in the hadron resonance gas model [51]. As for the freeze-out temperature  $T_{CF}$ , we follow the method in [49] and employ the experimentally measured skewness of the net-proton multiplicity distribution to determine  $T_{CF}$  for every collision energy, i.e.,

$$R_{32}^B(T_{CF}) = R_{32}^p(T_{CF}), \quad (31)$$

where  $R_{32}^B = \chi_3^B/\chi_2^B$  on the l.h.s. is calculated from the theory and that on the right is the skewness of the net-proton distribution measured in the experiment. See the left-top panel in Fig. 7. Notice that cumulants of net-baryon and net-proton number distributions are assumed implicitly to be equal to each other in Eq. (31). Finally, the resulting values of  $T_{CF}$  as well as  $\mu_{B_{CF}}$  for different collision energies are given in Tab. I. Furthermore, in Tab. I we also show the pseudocritical temperature  $T_c$  extracted from the inflection point of the chiral order parameter, i.e., the expectation value of the sigma field  $\langle\sigma\rangle$  as a function of  $T$  with  $\mu_B$  fixed, which in fact give the pseudocritical line in comparison to the freeze-out line. In what follows we will calculate the baryon number fluctuations both on the freeze-out line and the pseudocritical line.

In Fig. 7 we show the dependence of baryon number fluctuations  $R_{32}^B$ ,  $R_{42}^B$ ,  $R_{62}^B$ , and  $R_{82}^B$  on the center-of-mass collision energy, which is calculated in the LEFT within the fRG approach on the freeze-out line and pseudocritical line as presented in Tab. I. The theoretical calculations are also confronted with experimental measurement of cumulants of the net-proton distributions in the beam energy scan experiments from the STAR collaboration. The skewness ( $R_{32}^p$ ) and kurtosis ( $R_{42}^p$ ) of the net-proton distributions are measured in Au+Au collisions with centrality 0-5%, transverse momentum range  $0.4 < p_T$  (GeV/c)  $< 2.0$ , and rapidity  $|y| < 0.5$ , cf. [40] for more details. The preliminary result for the six-order cumulant of the net-proton distribution are obtained at two values of the collision energy, i.e.,  $\sqrt{s_{NN}}=200$  GeV and 54.4 GeV with centrality 0-40% [41, 42].

## V. SUMMARY AND OUTLOOK

### ACKNOWLEDGMENTS

## Appendix A: Glue potential

As we have discussed in Sec. II, the dynamics of the glue sector in QCD is partly imprinted in the glue potential  $V_{\text{glue},k}(A_0)$ , cf. Eq. (3), when the RG scale is in the regime of LEFT. We neglect the scale dependence of the glue potential in this work, and assume

$$V_{\text{glue}}(L, \bar{L}) = V_{\text{glue},k=0}(A_0) = T^4 \bar{V}_{\text{glue}}(L, \bar{L}), \quad (\text{A1})$$

where we have introduced a dimensionless glue potential  $\bar{V}_{\text{glue}}$ , and the dependence of the

The infrared cut-off dependence of the glue potential, i.e., the first term on the r.h.s. of Eq. (3), is neglected in this work, and it is parameterized as follows

$$V_{\text{glue}}(L, \bar{L}) = -\frac{a(T)}{2} \bar{L}L + b(T) \ln M_H(L, \bar{L}) + \frac{c(T)}{2} (L^3 + \bar{L}^3) + d(T) (\bar{L}L)^2, \quad (\text{A2})$$

Now come to the gluon part, we involve the gluon effect by the glue potential which is related to the Polyakov loop with temporal gluonic background  $A_0$

$$L(\mathbf{x}) = \frac{1}{N_c} \langle \text{Tr } \mathcal{P}(\mathbf{x}) \rangle, \quad \bar{L}(\mathbf{x}) = \frac{1}{N_c} \langle \text{Tr } \mathcal{P}^\dagger(\mathbf{x}) \rangle, \quad (\text{A3})$$

the Polyakov loop has the form of

$$\mathcal{P}(\mathbf{x}) = \mathcal{P} \exp \left( ig \int_0^\beta d\tau A_0(\mathbf{x}, \tau) \right). \quad (\text{A4})$$

The glue potential which we employed in the model, see [52], is parameterized as the form below

$$U_{\text{glue}}(L, \bar{L})/T^4 = -\frac{a(T)}{2} \bar{L}L + b(T) \ln M_H(L, \bar{L}) + \frac{c(T)}{2} (L^3 + \bar{L}^3) + d(T) (\bar{L}L)^2. \quad (\text{A5})$$

$M_H(L, \bar{L})$  stands for the Haar measure which is defined as

$$M_H(L, \bar{L}) = 1 - 6\bar{L}L + 4(L^3 + \bar{L}^3) - 3(\bar{L}L)^2. \quad (\text{A6})$$

Then we give the parametric form of the factors of the  $a, b, c, d$ . The factor  $a, c, d$  have the same form

$$x(T) = \frac{x_1 + x_2/t_c + x_3/t_c^2}{1 + x_4/t_c + x_5/t_c^2}, \quad (\text{A7})$$

and the form of  $b$  is

$$b(T) = b_1 t_c^{-b_4} (1 - e^{b_2/t_c^{b_3}}), \quad (\text{A8})$$

the values of the parameters are fixed by the thermodynamics and can be found at [52]. The temperature  $t_c$  is reduced temperature by  $t_c = (T - T_c)/T_c$ . We rescale the reduced temperature to make the glue potential accord with the Yang-Mills theory by  $(t_c)_{YM} \rightarrow \alpha(t_c)_{\text{glue}}$ , and  $(t_c)_{\text{glue}} = (T - T_c^{\text{glue}})/T_c^{\text{glue}}$ . Here we choose  $\alpha = 0.7$  and  $T_c^{\text{glue}} = 270$  MeV by fitting the kurtosis of the baryon number fluctuation with the lattice results. The effect of the Polyakov loop is working on the fermion distribution function see [53].

## Appendix B: Threshold functions

For the purpose of solving the flow equation of the effective potential Eq. (6) we use the Tylor expansion approach around the expansion point  $\kappa$ . The renormalised effective potential under the Tylor expansion is

$$\bar{U}_k(\bar{\rho}) = \sum_{n=0}^{N_u} \frac{\bar{\lambda}_{n,k}}{n!} (\bar{\rho} - \bar{\kappa}_k)^n, \quad (\text{B1})$$

with  $\bar{U}_k(\bar{\rho}) = U_k(\rho)$ ,  $\bar{\lambda}_{n,k} = \lambda_{n,k}/(Z_{\phi,k})^n$ ,  $\bar{\rho} = Z_{\phi,k}\rho$ ,  $\bar{\kappa}_k = Z_{\phi,k}\kappa_k$ . Here we take  $N_u = 5$  for the well convergence of effective potential. The running cutoff scale dependent expansion point  $\kappa_k$  is employed in our numerical calculation. Then we can get the Tylor expansion flow equation from Eq. (6) and Eq. (B1)

$$\begin{aligned} & \left. \partial_{\bar{\rho}}^n \left( \partial_t |_{\rho} \bar{U}_k(\bar{\rho}) \right) \right|_{\bar{\rho}=\bar{\kappa}_k} \\ &= (\partial_t - n\eta_{\phi,k}) \bar{\lambda}_{n,k} - (\partial_t \bar{\kappa}_k + \eta_{\phi,k} \bar{\kappa}_k) \bar{\lambda}_{n+1,k}. \end{aligned} \quad (\text{B2})$$

There is another chosen of the expansion point i.e. fixed point which the bare  $\kappa$  is independent on the cutoff scale which has a good convergence property of  $N_u$ , see, e.g.[28, 54]. However, the fixed point expansion may introduce temperature dependence into the Tylor expansion and the thermodynamics will be influence by this property, so we choose the running point expansion in this work. The running point is the solution of the equation of motion

$$\left. \frac{\partial}{\partial \bar{\rho}} \left( \bar{U}_k(\bar{\rho}) - \bar{c}_k (2\bar{\rho})^{\frac{1}{2}} \right) \right|_{\bar{\rho}=\bar{\kappa}_k} = 0. \quad (\text{B3})$$

We emphasize that the equation of motion must be satisfied under every value of the infrared cutoff. The renormalised explicit symmetry breaking term is  $\bar{c}_k = c/(Z_{\phi,k})^{1/2}$ , with the flow  $\partial_t \bar{c}_k = (1/2)\eta_{\phi,k} \bar{c}_k$ . From Eq. (B2) and Eq. (B3) we can obtain the flow of the renormalised running expansion point

$$\begin{aligned} \partial_t \bar{\kappa}_k &= -\frac{\bar{c}_k^2}{\bar{\lambda}_{1,k}^3 + \bar{c}_k^2 \bar{\lambda}_{2,k}} \left[ \partial_{\bar{\rho}} \left( \partial_t |_{\rho} \bar{U}_k(\bar{\rho}) \right) \right]_{\bar{\rho}=\bar{\kappa}_k} \\ &+ \eta_{\phi,k} \left( \frac{\bar{\lambda}_{1,k}}{2} + \bar{\kappa}_k \bar{\lambda}_{2,k} \right). \end{aligned} \quad (\text{B4})$$

In this work we don't consider the field dependence of the Yukawa coupling and the renormalised Yukawa coupling is  $\bar{h}_k = h_k/(Z_{\psi,k} Z_{\phi,k}^{1/2})$ .

Now we give the ultraviolet of the flow equations i.e. the initial conditions of the differential equations. The ultraviolet cutoff scale is set to  $\Lambda = 700$  MeV. The parameterized effective potential at UV point is

$$U_{k=\Lambda}(\rho) = \frac{\lambda_{k=\Lambda}}{2} \rho^2 + \nu_{k=\Lambda} \rho, \quad (\text{B5})$$

The values of the parameters in the effective potential are  $\lambda_{k=\Lambda} = 11$  and  $\nu_{k=\Lambda} = (0.830 \text{ GeV})^2$ . In addition, the initial values of the explicit chiral symmetry breaking strength and Yukawa coupling are  $c = 2.82 \times 10^{-3} \text{ GeV}^3$

and  $h_{k=\Lambda} = 10.18$ . These parameters are fixed by fitting the vacuum physical observables, i.e.,  $f_\pi = 92 \text{ MeV}$ ,  $m_\psi = 300 \text{ MeV}$ ,  $m_\pi = 136 \text{ MeV}$ , and  $m_\sigma = 479 \text{ MeV}$ .
